²Department of Plant Systematics, Faculty of Biology and Environmental Protection, University of Silesia, Jagiellońska 28, 40-032 Katowice, Poland

Abstract: A full list of extinct and endangered archaeophyte species for Poland is presented according to IUCN categories. The species are analysed in respect of their origin and syntaxonomic classification. Endangered archaeophytes should be cultivated in botanical gardens and open-air museums, and next reintroduced to natural sites.

Keywords: archaeophytes, archaeophyta anthropogena, endangered species, plant origin, origin of archaeophytes, Poland

1. Introduction

Archaeophytes are alien plant species that have been introduced to a region before the discovery of America. Thus they are a group of old anthropophytes (i.e. plants accompanying humans), distinguished within the floras of Europe. In Poland, the oldest among them appeared with the onset of Neolithic agriculture. Several hypotheses on their origin have been presented, some of them well-documented more, some less so (Zając 1979). They are segetal (i.e. field weeds) or ruderal plants. Many of them have adapted to traditional methods of cultivation or to specific ruderal habitats. The changing techniques of cultivation, preparation of seeds for sowing, and the disappearance of old ruderal habitats, brought about the massive disappearance of these plants. A significant proportion of species classified in this group are identified as threatened to various degrees. The extinction of these species would impoverish the biodiversity of our flora. Thus it is necessary to undertake measures that can save this group of vascular plants, both within the borders of various countries and within the European context. In many European countries these species have become extinct, as indicated in red lists and red data books especially for Central and Northern Europe (i.e. Čerňovský *et al.* 1999; Kotiranta *et al.* 1998; Niklfeld 1999; Ludwig & Schnittler 1996).

2. Material and methods

The term “archaeophyte” is rather clearly defined in the European literature (Kornaś & Medwecka-Kornaś 2002; Kukkonen 1995; Scholz 1995). It is impossible to prepare a list of archaeophytes for the whole territory of Europe, or even for Central Europe; it is possible only for individual countries. In this study, we used the list of archaeophytes for Poland published and next updated by Zając (1983, 1987a, 1987b, 1988), later verified by Zając *et al.* (1998). This list, since its first publication, has been changed and supplemented in relation to our growing knowledge about alien plants in Poland.

To assess the threat for particular species, we used data from the ATPOL database (Zając 1978) and cartogram maps (Zając A. & Zając M. 2001). More recent floristic records have been also obtained from published and unpublished sources gathered by other botanists.

In the *Polish Plant Red Data Book* (Kaźmierczakowa & Zarzycki 2001), 6 species of archaeophytes were included, but in the “Red List of Vascular Plants in Poland” (Zarzycki & Szelağ 2006), their number reached 34 species. In comparison with the latter publication, the present paper includes major changes in classifying species to particular categories of threat (IUCN 1994).

We follow the classification used by Kaźmierczakowa & Zarzycki (2001). The most useful category was DD (Data Deficient), which includes species with still insufficient data, but which should be regarded as threatened.

3. Results

3.1. The red list of archaeophytes in Poland

In Poland, some 165 species are regarded as archaeophytes. Out of this number, 74 taxa, representing ca. 44.8% of the total, are classified as extinct or more or less threatened (Appendix, Fig. 1). It is a significant proportion, much higher than indicated for native components of the flora (21%, Zarzycki & Szelağ 2006). Five species have become extinct in the territory of Poland (5 taxa). However, they have suffered a similar fate throughout their distribution area. More taxa are critically endangered (13 species): they occur only in very few stations and are disappearing throughout their historical distribution range. At the stations where they still occur, their numbers are low, so if special measures are not taken, they will probably be soon classified as extinct. Endangered taxa (16 species) are a group with a high probability of becoming extinct, but over a longer time horizon. These species have already lost most of their historical habitats, but still occur in many stations and in populations numerous enough to be saved by humans without major efforts. The largest group are vulnerable taxa (31 species). They are evidently in retreat, but still have a fairly high number of stations, at least in some areas. Many of these species die out at the fringes of their distribution ranges, or become less frequent throughout their previous ranges (this pertains to the species that do not have evident limits of distribution

within the territory of Poland). Nine species were classified as facing minor risk. This group includes the taxa for which the level of risk has not been established yet (because they are often not distinguished from their close relatives, e.g. *Aphanes microcarpa*) or those whose satisfactory status is a temporary condition (e.g. *Avena strigosa*, which could come under pressure of extinction soon after agricultural practices change).

This high proportion of species of archaeophytes classified under IUCN categories indicates that in Poland this historical/geographical group of synanthropic taxa is among those most endangered. Taking into consideration how this group, unlike any other, is affected by human economic activities, it should be the focus of attention and be specially protected by the society.

3.2. Origin of threatened species

Archaeophytes arrived in Poland often in distant past and not directly from their homelands, but in stages, as they accompanied the Neolithic people who gradually colonized more distant and less suitable areas of Europe. It is difficult to determine what kind of threat to their existence they face in their hypothetical homelands. For the archaeophytes occurring in Poland, the hypotheses regarding their origin have been presented in a number of publications (Zając 1983, 1987a, 1987b, 1988). These species come from geographically diverse areas. Their hypothetical areas of origin (Appendix), in the case of segetal weeds, only partly overlap with the areas of primary natural occurrence of wild species of cereals (the Fertile Crescent). Most often these are species that became weeds in the areas of secondary extension of cultivated lands, by the migration of early agricultural peoples into Central Europe. Homelands of those plants are often identified as a large region, such as the entire Mediterranean subkingdom or Irano-Turanian subkingdom, or these species originally were a part of the Mediterranean-Irano-Turanian connecting element. The archaeophytes occurring in ruderal sites also have a very broad spectrum of areas where they most probably occur as native species. Taking into consideration the areas from where the subsequent migration waves of peoples settling in Central Europe arrived, this approach is fully justified.

An essential group among archaeophytes are those classified as *archaeophyta anthropogena* (Mirek 1981). These are taxa that have evolved owing to humans. In Poland, 21 such species occur, and our list includes as many as 18 of them. These are taxa that have been selected by humans from natural populations growing within Poland, such as *Rhinanthus alecterolophus* subsp. *bucalis*, *R. serotinus* subsp. *apterus*, and *Odontites verna*. The evolution of their diaspores has led to ever closer likeness to the grains of the caryopsis of cereals and which disperse by speirochory (i.e. accidental dispersal

Fig. 1. Numbers of archaeophyte species extinct and threatened with extinction in Poland

Explanations: EX – extinct, CR – critically endangered, EN – endangered, VU – vulnerable, DD – data deficient, 1 – only segetal, 2 – only ruderal, 3 – both segetal and ruderal

with seeds). The taxa dispersing together with a cultivated plant include the weeds of flax fields (*Camelina alyssum* subsp. *alyssum*, *Cuscuta epilinum*, and *Spergula arvensis* subsp. *maxima*), which are most likely extinct from the area of Poland (and perhaps even throughout their range).

The extinction or disappearance of these taxa is particularly dangerous, because they do not occur anywhere in natural communities. They have evolved as a result of selection by humans, so humans should now set about saving them.

3.3. Synecological characteristics of threatened species

Among the 74 species covered in this contribution, 58 are segetal weeds, 13 are ruderal plants, and 3 species occur in both types of habitats. The segetal weeds include first of all species from plant associations of the alliance *Caucalidion platycarpi*. In Poland they occur on soils with a higher calcium carbonate content: rendzinas, black soils, and alluvial soils along water courses. There are 19 species closely associated with this alliance, and 10 others occur mostly within it, but they manifest a broader ecological spectrum. The 4 species of weeds of flax fields occur in associations classified in the order *Lolio remotae-Linetalia*. The remaining weeds occur in various associations of the order *Sperguletalia arvensis*.

The archaeophytes occurring in ruderal sites are included in quite diverse classes. *Coronopus procumbens* and *Sclerochloa dura* occur in associations of the class *Polygono arenastrii-Poetea annuae*, on dry roadsides. Species like *Solanum alatum* and *Chenopodium vulvaria* occur in associations of the subclass *Sisymbrietea*. In drier and more xerothermic ruderal associations of the order *Onopordetalia acanthii*, species like *Marrubium vulgare* and *Hyssopus officinalis* occur.

Because of the fairly uniform synecological affiliation of most of the segetal weeds, they seem to be easier to protect or reintroduce. The species of archaeophytes liable to extinction require diversified habitats with specific requirements of soil type and ambient temperatures. Many of these are relics of cultivation, most often medicinal plants or spices, such as *Marrubium vulgare* and *Hyssopus officinalis* mentioned above, or *Parietaria officinalis* and *Anthriscus cerefolium* var. *cerefolium*.

3.4. Synthetic data on the distribution of endangered taxa

The floristic database developed for the purposes of the *Distribution atlas of vascular plants in Poland* (Zajac A. & Zajac M. 2001) was used here to generate combined maps for several groups of species (Fig. 2). In each cartogramme unit (10 km x 10 km) of the ATPOL database (see <http://www.ib.uj.edu.pl/en/>), the

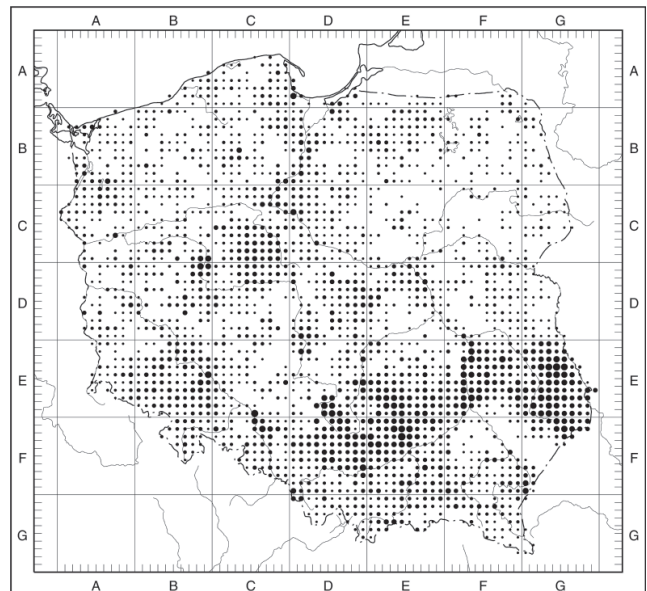

Fig. 2. Concentrations of segetal archaeophytes threatened with extinction in Poland, which occur in communities of the alliance *Caucalidion platycarpi*

diameter of circles represents the number of species of archaeophytes found in the unit. The most endangered and the largest group of the alliance *Caucalidion platycarpi* inhabits principally the uplands of southern Poland. In this region also the most endangered and rarest species show the highest level of fidelity to this syntaxon. There is also one more centre of their distribution, although less evidently marked, covering the central part of Greater Poland (Wielkopolska); namely the Kuyavia (Kujawy) region and the lower section of the Vistula river. However, the species occurring there have a wider distribution and are less characteristic for

Fig. 3. Concentrations of segetal archaeophytes threatened with extinction in Poland, which occur in communities other than those belonging to *Caucalidion platycarpi*

this alliance. The fact that the most valuable archaeophytes are confined to a certain part of Poland enhances the danger to this group, as the distribution of their joint occurrence is very limited.

The remaining segetal species (Fig. 3) still occur in larger areas and are absent only from north-eastern Poland and much rarer in the Western Pomeranian region. These species are mainly classified as vulnerable (V), thus less threatened with extinction.

Fig. 4. Concentrations of ruderal archaeophytes threatened with extinction in Poland

The distribution of species associated with ruderal habitats is very interesting (Fig. 4). The highest concentration of their stations is found in Lower Silesia. In the remaining part of Poland they are associated with centres of the early settlement period, such as Kraków, Poznań, Toruń, Gdańsk, Puławy, and Lublin. The ruderal flora of these cities undergoes rapid modifications, so that habitats change and these species are almost equally divided into endangered (E) and vulnerable (V).

We did not consider here the group distributions of extinct weeds of flax fields, which once were dispersed throughout Poland, and 2 species of the genus *Solanum* (*S. alatum* and *S. luteum*) and 2 subspecies of *Rhinanthus*, for which the distribution maps in Poland have not been elaborated yet.

3.5. Causes of extinction and ways to prevent it (restitution and reintroduction)

The causes of the disappearance of species from segetal and ruderal habitats are complex and very different from each other. The segetal weeds found mainly in plant associations on soils richer in calcium carbonate are disappearing, chiefly because of seed cleaning and excessive use of chemicals in agriculture. The elimina-

tion of specialised speirochorous species could be illustrated using the example of weeds of flax fields. These were adapted to traditional methods of seed cleaning, and the modern mechanical methods of cleaning eliminated them altogether. At present these weeds are extinct in Poland. A similar situation occurs with respect to many barochorous species (i.e. dispersed only by gravity), such as *Conringia orientalis*, *Bupleurum rotundifolium*, *Nigella arvensis*, and *Vaccaria pyramidata*, and species of the alliance *Caucalidion platycarpi*, which are speirochorous.

The disappearance of ruderal weeds is connected with the changes occurring in habitats, principally in cities, as it is demonstrated in their distribution map (Fig. 4). Cities in the past provided suitable living conditions for high numbers of these plants. The ruderal species that have vanished recently, are associated with sites rich in ammonia nitrogen, and with fertile soils rich in humus. This type of habitats is disappearing quickly. Town and cities have become cleaner, and anthropogenic soils usually contain there a high proportion of gravel, etc., which does not favour the development of such weeds.

In our opinion the only possibility of saving these disappearing archaeophyte species could be to reintroduce them in large numbers into habitats kept under constant supervision. Most of the diaspores can still be obtained from Polish plants. Perhaps a closer inspection of flax fields in north-eastern Poland may still reveal some weeds associated with flax (in the sowing material still cleaned by traditional methods).

The disappearing oldest segetal weeds – archaeophytes – should be reintroduced into substitute habitats. They may be saved by *ex situ* cultivation. The places suitable for such protective measures could include botanical gardens and open-air museums and preserved old buildings (parts of ethnographic parks).

Some botanical gardens in Poland are large (e.g. 64 ha in Łódź, 40 ha in Powsin near Warsaw, 22 ha in Poznań), so some weeds are cultivated on separate lots. Also open-air museums are usually quite large, preserving examples of old rural architecture, and are particularly well-suited as the sites to protect segetal weeds on special fields with cereal plants. If crop seeds with a high proportion of speirochorous weed diaspores are applied, and the remaining species are sown additionally into the soil, the segetal weeds can be effectively protected. Open-air museums can also be used to provide suitable habitats for ruderal weeds. These will only require more precise measures when preparing the substrate.

Open-air museums and botanical gardens are not uniformly located throughout Poland. If we get to know the distribution ranges and ecological requirements of various species, we can design *ex situ* cultivation in suitable sites with favourable climatic conditions.

4. Discussion

Due to our growing knowledge about alien plant species in Poland, the lists for particular groups of anthropophytes can be modified. In this paper we present the list of endangered archaeophytes for Poland with some changes. For example, *Hyssopus officinalis* and *Marrubium vulgare* are included here, whereas previously they have been considered as kenophytes (=neophytes) (Zajac *at al.* 1998; Tokarska-Guzik 2005). In the last publication those species on the ground of historical sources were described as the "oldest" arrivals among kenophytes, present in the 16th and 17th century flora of Poland (Tokarska-Guzik 2005). As mentioned above, in the *Polish Plant Red Data Book* (Kaźmierczakowa & Zarzycki 2001), only 6 species of archaeophytes were included, but their classification is similar to the one presented here. In the „Red List of Vascular Plants in Poland” (Zarzycki & Szelaĝ 2006), 34 species of archaeophytes are included, but their classification is only partially similar to ours. Comparisons are difficult, because the first publication does not include the category critically endangered (CR). Because of this, the 2 categories (CR and EN) were considered jointly here. In most cases in the list presented here, the degree of threat is higher. It means that there is a need to verify our knowledge about the current distribution of archaeophytes, connected with both segetal and ruderal habitats, to assess the real degree of its threat. In our

opinion, it is necessary to distinguish the category CR to show the most endangered group of species.

5. Conclusions

1. In Poland, more than 165 archaeophyte species have been identified. Out of this number, 74 are classified as extinct or disappearing: 5 extinct (EX), 13 critically endangered (CR), 16 endangered (EN), 5 vulnerable (VU), and 9 data-deficient (DD).

2. Among the disappearing archaeophyte species, special attention should be paid to those whose evolution has been assisted by humans and are classified as *archaeophyta anthropogena*. The total number of such species in Poland is 21, and as many as 18 of them are threatened.

3. The greatest number of endangered segetal weeds is found within associations of the alliance *Caucalidion platycarpi*, on soils rich in calcium carbonate.

4. The distribution of disappearing species of archaeophytes in Poland is not uniform. Their numbers are highest in the uplands of southern Poland. Ruderal species are most numerous in oldest cities and in Lower Silesia.

5. These species can be saved only by *ex situ* cultivation in botanical gardens and open-air museums. Entire communities of segetal weeds can be reconstructed and suitable conditions for ruderal species can be found there.
